Blood cells are derived from a common set of hematopoietic stem cells, which differentiate into more specific progenitors of the myeloid and lymphoid lineages, ultimately leading to differentiated cells. This developmental process is controlled by a complex regulatory network involving cytokines and their receptors, transcription factors, and chromatin remodelers. Using public data and data from our own molecular genetic experiments (quantitative PCR, Western blot, EMSA) or genome-wide assays (RNA-sequencing, ChIP-sequencing), we have assembled a comprehensive regulatory network encompassing the main transcription factors and signaling components involved in myeloid and lymphoid development. Focusing on B-cell and macrophage development, we defined a qualitative dynamical model recapitulating cytokine-induced differentiation of common progenitors, the effect of various reported gene knockdowns, and the reprogramming of pre-B cells into macrophages induced by the ectopic expression of specific transcription factors. The resulting network model can be used as a template for the integration of new hematopoietic differentiation and transdifferentiation data to foster our understanding of lymphoid/myeloid cell-fate decisions.

gene network | dynamical modeling | hematopoiesis | cell fate | cell reprogramming

Hematopoiesis is the process through which all blood cells are produced and renewed, starting from a common population of hematopoietic stem cells (HSCs) (1). HSCs differentiate into lineage-specific progenitors with restricted differentiation potential and expressing specific surface markers (Fig. 1A). Loss- or gain-of-function experiments targeting transcription factors (TFs) or signaling components have led to the identification of factors required for specific developmental steps. Some factors are required for the development of entire lineages (e.g., Ikaros for lymphoid cells), whereas others are needed only at late stages of cell-type specification (e.g., the requirement for the paired-box factor Pax5 after the pro-B-cell stage). These factors cross-regulate each other to activate one gene-expression program and silence alternative ones.

Although cell commitment to a specific lineage was long considered irreversible, recent reprogramming experiments emphasized the pervasive plasticity of cellular states. Indeed, the ectopic expression of various regulatory factors (mainly TFs and signaling components) can enforce the establishment of new gene-expression programs in many kinds of differentiated cells (2). Strikingly, pluripotency can be induced in somatic cells by forcing the expression of a handful of TFs, enabling further differentiation into any cell type (3). In the hematopoietic system, TF-induced transdifferentiation between erythroid and myeloid cells and between lymphoid and myeloid cells has been described (4).

In this study, we focus on B-cell and macrophage specification from multipotent progenitors (MPs) and on TF-induced transdifferentiation between these lineages. Ectopic expression of the myeloid TF C/EBP α (CCAAT/enhancer-binding protein alpha, encoded by the Cebpa gene) can induce B cells to transdifferentiate into macrophages (Fig. 1A, red arrows) (5). C/EBP α is also required

for the transition from common myeloid progenitors (CMPs) to granulocyte-macrophage progenitors (GMPs), and mutation in this gene can result in acute myeloid leukemia (6). Understanding the molecular mechanisms by which such factors can induce cell-fate decisions is of primary importance and might help in the development of novel therapeutic strategies.

Computational modeling of regulatory networks is increasingly recognized as a valuable approach to study cell-fate decisions. Indeed, the integration of the available information about gene regulation into a common formal framework allows us to identify gaps in our current knowledge, as successfully shown in previous studies on the differentiation of hematopoietic cells (7). Dynamic analysis can reveal nontrivial properties, including transient phenomena, and can be used to identify key regulatory factors or interactions involved in the control of cell-fate commitment (8, 9). Furthermore, genome-wide approaches such as ChIP-sequencing (ChIP-seq) can unveil novel regulations to be further incorporated in a gene-network model (10). Here, we combined a logical multilevel formalism, capturing the main qualitative aspects of the dynamics of a regulatory network in the absence of quantitative kinetic data (11), with a meta-analysis of all available ChIP-seq datasets for a selection of TFs, revealing tens of previously unknown regulations. We then performed iterations of computational simulations, followed by comparisons with experimental data and adjustments of the model, to identify caveats in our model and to test the effect of putative regulations in silico before confirming them experimentally (Fig. 1B).

This paper results from the Arthur M. Sackler Colloquium of the National Academy of Sciences, "Gene Regulatory Networks and Network Models in Development and Evolution," held April 12–14, 2016, at the Arnold and Mabel Beckman Center of the National Academies of Sciences and Engineering in Irvine, CA. The complete program and video recordings of most presentations are available on the NAS website at www.nasonline.org/Gene_Regulatory_Networks.

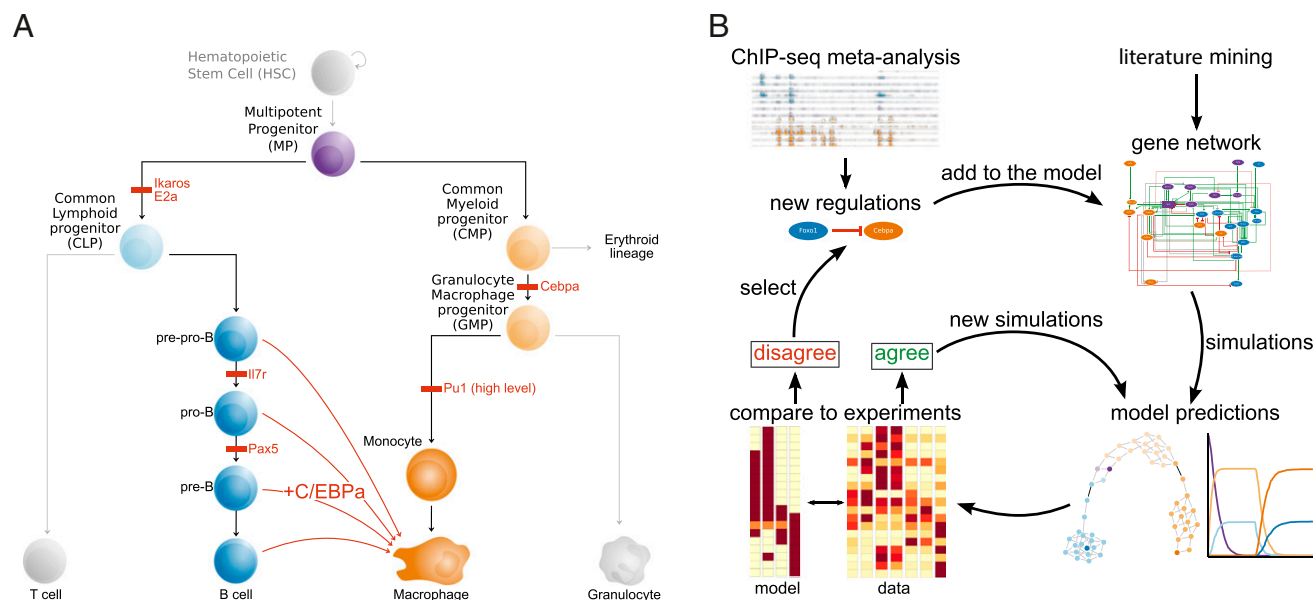

Fig. 1. (A) Schematic representation of hematopoietic cell specification. Genes in red are required for progression at the corresponding steps. *C/EBPα*-induced transdifferentiation is indicated by red arrows from B-lineage cells to macrophages. (B) Iterative modeling workflow. A model is first built based on the literature and is used to predict dynamical behaviors (cell phenotype, differentiation, reprogramming, and so forth). Predictions then are compared with experimental data; when the predictions and experimental data agree, further predictive simulations are performed; when they do not agree, further regulations are inferred from ChIP-seq data and are integrated into the model until simulations fully agree with data.

Results

Gene Network Controlling B-Cell and Macrophage Specification. To build a model of the gene-regulatory network controlling B-cell and macrophage specification from common progenitors, we first performed an extensive analysis of the literature to identify the TFs and signaling pathways controlling these events. The TF PU.1 (encoded by the *Spi1* gene) is required for the normal development of both lymphoid and myeloid cells (12). The development of common lymphoid progenitors (CLPs) depends on the TFs Ikaros (encoded by *Ikzf1*) and E2a (encoded by the transcription factor 3 gene *Tcf3*) (Fig. 1A) (13, 14). The B-cell lineage is further controlled by Mef2c, the interleukine 7 receptor (IL7r), Ets1, Foxo1, Ebf1, and Pax5 (15, 16, 17). The specification of the myeloid GMPs depends on *C/EBPα* (6), which is regulated by Runx1 (runt-related transcription factor 1) (18). Macrophage specification further relies on the macrophage colony-stimulating factor (M-CSF) receptor (CSF1r), on the up-regulation of PU.1, and on Cebpb and the Id proteins (including Id2) (19, 20). The TFs Egr and Gfi1 repress each other to specify macrophage versus granulocyte lineages (21); Gfi1 also is important for B-cell differentiation (22).

Finally, to distinguish among the different cell types, we further consider the B-cell marker CD19, the macrophage marker Mac1 (also called “Cd11b,” encoded by the *Itgam* gene), and the cytokine receptor Flt3, which is expressed specifically on MPs and CLPs.

We then carried out an extensive review of the literature to collect information about cross-regulations between the selected factors and grouped these regulations into four classes, depending on the available evidence: (i) functional effect, e.g., an effect inferred from gain- or loss-of-function experiments (which could be either direct or indirect); (ii) physical interaction, e.g., TF binding at a promoter or enhancer; (iii) physical and functional evidence, suggesting a direct regulation; and (iv) fully proven regulation, e.g., evidence of functional effect and physical interaction along with reported binding-site mutations affecting the functional effect or reporter assays demonstrating *cis*-regulatory activity. Altogether, we gathered a total of 150 items of experimental evidence (Dataset S1) supporting 79 potential regulations (Fig. S1A).

Many of these regulations are sustained only by functional evidence. To assess whether they could correspond to direct regulations, we analyzed public ChIP-seq datasets targeting each of the TFs considered in our network, amounting to 43 datasets for 10 TFs in total (Dataset S2). We systematically looked for peaks in the “gene domain” (23) coding for each component involved in the network (Materials and Methods). This ChIP-seq meta-analysis confirmed 26 direct regulations (Fig. 2A, green or red cells with a star) and pointed toward 66 additional potential transcriptional regulations (gray cells with a star). For example, at the *Spi1* locus, we confirmed the binding of Ikaros at known enhancers, where it was previously reported to limit the expression of *Spi1* together with a putative corepressor (24). Because we also found that Pax5, Ebf1, and Foxo1 bind to the same sites (Fig. 2B), we suggest that these factors could act as corepressors. Ectopic expression of Foxo1 in macrophages induced a reduction of *Spi1* expression (Fig. S1B), further confirming this negative regulation.

***C/EBPα* Directly Represses B-Cell Genes.** We have previously reported that *C/EBPα* can enforce B-cell TF silencing by increasing the expression of the histone demethylase Lsd1 (Kdm1a) and the histone deacetylase Hdac1 at the protein level and that these enzymes are required for the decommissioning of B-cell enhancers and the silencing of the B-cell program (25). Because key B-cell regulators such as Foxo1, Ebf1, and Pax5 are repressed after 3 h of *C/EBPα* induction (Fig. S1C), we wondered whether *C/EBPα* could be directly responsible for this early effect. To verify this hypothesis, we reanalyzed data from ChIP-seq for *C/EBPα* after 3 h of induction in a reprogrammable cell line (26). As expected, we detected binding of *C/EBPα* at the *cis*-regulatory elements of *Foxo1* (Fig. 2C), *Ebf1*, *Pax5*, *IL7r*, and *Mef2c* genes (Fig. S1C), supporting their direct repression by *C/EBPα*.

Furthermore, *C/EBPβ* also can induce transdifferentiation of pre-B cells (5), and it has been shown that *C/EBPβ* can rescue the formation of granulocytes in *C/EBPα*-deficient mice (27). Moreover, *C/EBPβ* almost always binds at *C/EBPα*-binding sites (Fig. 2A), as exemplified by the *Spi1* locus (Fig. 2B). These findings suggest a

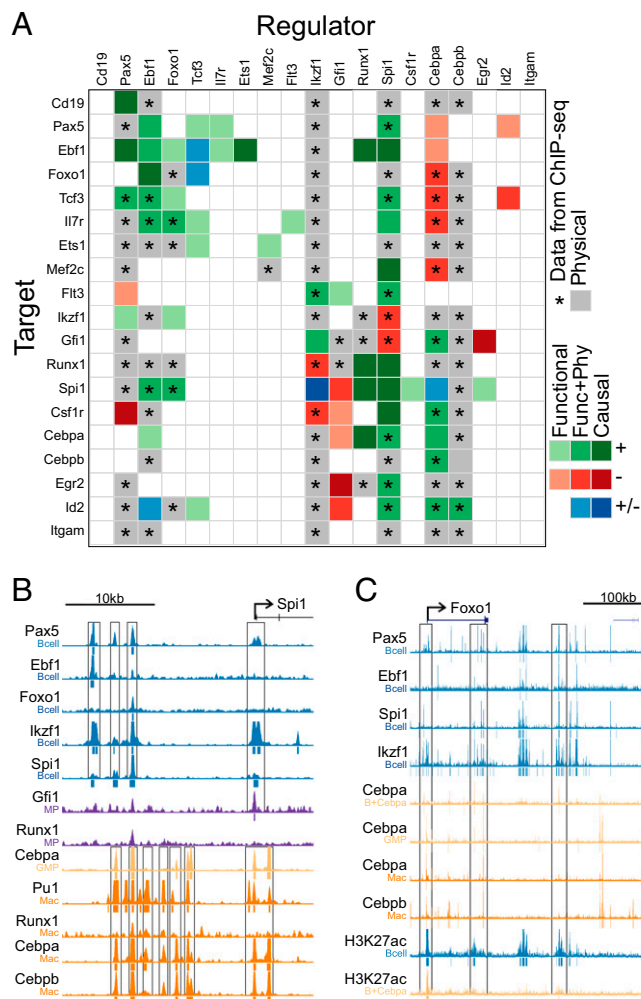

Fig. 2. (A) Heatmap showing the regulations inferred from the literature and from ChIP-seq meta-analysis. (B) ChIP-seq signals and peaks (under signal) at the *Spi1* locus. Black frames indicate known enhancers (24). The vertical axes represent reads per million (RPM) (maximum: 2 RPM for Ebf1 and Ikaros, 1.5 RPM for Foxo1, 1 RPM for Runx1 and Gfi1, 5 RPM for other TF). (C) ChIP-seq signals and peaks (under signal) at the *Foxo1* locus. Black frames indicate B-cell enhancers in which ζ /EBP α binding is detected. The vertical axes represent RPM (maximum: 2 RPM for Ebf1, 5 RPM for other TFs, 3 RPM for H3K27ac). Note that Pax5 and Ikaros peaks are located downstream of the first exon and all other peaks are upstream of the TSS.

redundancy between these two factors in the regulation of their target genes (at least in those considered here), and we integrated this redundancy in our model.

Dynamical Modeling Using Multilevel Logic. The core components and regulations collected from our analysis of the literature and ChIP-seq datasets were assembled in a regulatory graph using the GINsim software (Fig. 3).

Validating all the predicted regulations (Fig. 24, gray cells with a star) experimentally would be a daunting task. Instead, we focused on a selection of these regulations (depicted by the gray arrows in Fig. 3) and used dynamical modeling to assess their impact on cell specification.

To transform our regulatory graph into a predictive dynamical model, we took advantage of a sophisticated logical (multilevel) formalism. More precisely, we associated a discrete variable with each regulatory component. These variables usually take two values (0 or 1) but can be assigned more values whenever justified.

Regulations are combined into logical rules using the Boolean operators NOT, AND, and OR, to define the conditions enabling the activation of each model component (*Materials and Methods*). This formalism relies essentially on qualitative information and allows the simulation of relatively large network models (encompassing up to a few hundred components). It should be noted that the value 0 does not necessarily imply that a factor is not expressed at all but rather that its level is insufficient to affect its targets significantly. PU.1 is the only factor for which we found clear evidence supporting a distinction between two functional (non-0) levels (21). Consequently, we assigned a ternary variable (taking the values 0, 1, or 2) to this node and assigned Boolean variables (i.e., taking the values 0 or 1) to the other nodes.

Regarding the definition of the logical rules, we first considered the regulations supported by both functional and physical evidence (depicted as green and red arrows in Fig. 3). As a default, we required that all activators but no inhibitor to be present to enable target activation and further adjusted the rules based on information gathered from the literature (see the rules in *Materials and Methods* and [Dataset S3](#)). As mentioned before, we then added selected regulations inferred from our ChIP-seq meta-analysis (depicted as gray arrows in Fig. 3) to refine our model.

Modeling Different Cell-Type Phenotypes. We first assessed whether our model properly accounts for progenitor, B-cell, and macrophage gene-expression patterns. Because stable states capture the long-term behavior associated with the acquisition of gene-expression patterns during cell specification, we computed all the stable states of our model using GINsim software (28) and compared them with gene-expression data (Fig. 4A) (29). We initially found that our stable states were largely inconsistent with known patterns of gene expression (Fig. S2A), revealing important caveats in the published data on which we based our model.

A first caveat concerned the regulation of *Cebpa*. Indeed, *Cebpa* is not expressed in lymphoid cells, although its well-known activators PU.1 (*Sp1*) and Runx1 are expressed in both B cells and

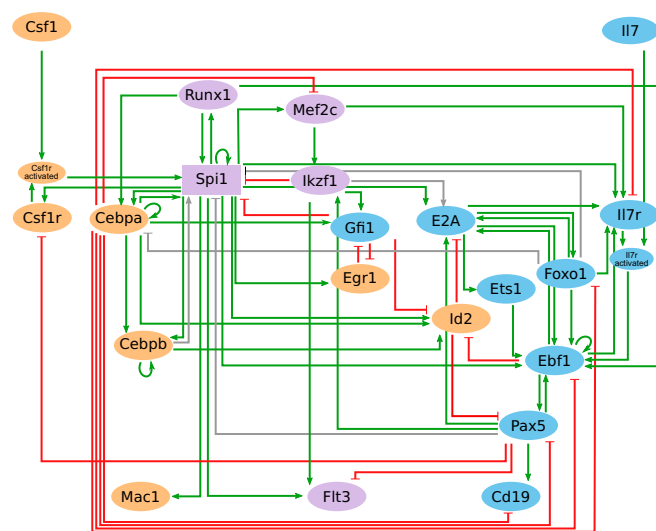

Fig. 3. A regulatory graph depicting the interactions inferred from the literature and ChIP-seq meta-analyses. Nodes represent genes (except for CSF1r_act and Il7r_act, which represent the activated forms of cytokine receptors), and arrows denote regulatory interactions. Orange nodes represent factors expressed in macrophages, purple nodes represent factors expressed in progenitors, and blue nodes represent factors expressed in B-lineage cells. Ellipses represent Boolean components; the rectangle emphasizes the ternary component *Spi1*. Green and red edges correspond to activations and inhibitions, respectively. Gray edges denote the regulations predicted by the ChIP-seq meta-analysis, which were included in the model to increase consistency with expression data.

macrophages. Therefore, our model exhibited only *Cebpa*⁺ stable states (Fig. S24), suggesting that an inhibitory regulation of *Cebpa* was missing during lymphoid specification. *Foxo1*, a factor controlling the early steps of B-cell commitment (30), stands as a relevant candidate. To test this hypothesis, we performed ChIP-seq for *Foxo1* in our pre-B-cell line and observed binding at the *Cebpa* promoter, suggesting a physical interaction and potential direct regulation of *Cebpa* (Fig. S2B). To test if *Foxo1* has a functional effect on *Cebpa* expression, we ectopically expressed it in a macrophage cell line (RAW) and found a significant down-regulation of *Cebpa* (Fig. S2C), suggesting a direct negative regulation of *Cebpa* by *Foxo1*. We therefore refined our initial model by including this additional regulation (see the rule associated with *Cebpa* in Dataset S3).

A second caveat revealed by our model analysis concerned the regulation of *Tcf3* (encoding E2a). Indeed, E2a was expressed in all the stable states, even after *Cebpa* repression by *Foxo1* was included (Fig. S2D), although E2a has been shown to be expressed in MPs and in lymphoid cells but not in myeloid cells. Moreover, the only factor in our model expressed in MPs and regulating E2a is PU.1, which is also known to be expressed in myeloid cells, thus suggesting a missing regulation of E2a. However, despite our efforts, we could not find any evidence for a myeloid repressor of E2a in either the literature or our ChIP-seq data meta-analysis. Turning to putative activators of E2a, we focused on Ikaros. Indeed, like E2a, Ikaros is required for lymphoid development, and its knockout entails a loss of lymphocytes similar to that seen with E2a knockout. Interestingly, we found that Ikaros binds the E2a promoter in B cells (Fig. S2E), suggesting a direct activation of E2a by Ikaros. Hence, we further refined our model by including this regulation (see the rule associated with E2a in Dataset S3).

More surprising was the high expression of *Egr2* observed in pro/pre-B cells. We also found expression of the related factor *Egr1* in two different datasets (Fig. S2F and G). It has been reported that *Egr1/2* cross-inhibits *Gfi1*, the first favoring macrophage specification and the second favoring B lineage (21). However, although this study shows that *Egr2* has an effect on the differentiation

potential of MPs, it does not demonstrate that this factor is indeed not expressed in B cells or that it can antagonize the expression of B-cell genes. To assess the expression of *Egr2*, *Egr1*, and *Gfi1* at the protein level, we performed Western blots for these proteins in B cells and macrophages. We were able to detect all three proteins in B cells (Fig. S2H), confirming the gene-expression data. We therefore propose that some late B-cell factors activate both *Gfi1* and *Egr2*, overcoming their cross-inhibitions. Because *Pax5* was the only B-cell factor found in our meta-analysis to bind to *Gfi1* and *Egr2* loci (Fig. 24), we consider it to be an activator of both *Gfi1* and *Egr2* (see corresponding rules in Dataset S3).

When analyzing the resulting refined model, we found that its stable states correspond well to CLPs, GMPs, B-lineage cells, and macrophages, as defined by the known patterns of gene expression (Fig. 4B). For some genes, we obtained apparent discrepancies between expression data and stable state values; these discrepancies can be attributed to model discretization (see SI Materials and Methods for more details).

Our analysis points to previously unrecognized regulators of E2a and *Cebpa* that are important at the onset of lymphoid and myeloid specification and introduces refinements of the regulations of *Egr2* and *Gfi1*. After incorporating these regulations in our model, we used it to study the dynamics of B-cell and macrophage specification.

Specification of B-Cell and Macrophage Precursors from MPs. To improve our understanding of the transcriptional regulation of hematopoietic cell specification, we performed several iterations of hypothesis-driven simulations and comparisons with experimental data, followed by model modifications to solve remaining discrepancies.

First, using GINsim software, we simulated the specification of MPs, defined by the expression of *Spi1*, *Runx1*, *Ikzf1*, *Gfi1*, and *Flt3*. In the absence of environmental signals, we found that our model can lead to two different stable states corresponding to GMPs and CLPs (Fig. 5A). Upon stimulation with both CSF1 and IL7, the system tends to two new stable states, corresponding to macrophages and B lineage cells, respectively. These simulations thus recapitulate the commitment of cells to GMP- and CLP-associated states and their loss of potential for alternative lineages.

Next, using stochastic simulations (see Materials and Methods and ref. 31 for more details), we analyzed the evolution of the fraction of cells expressing distinct factors associated with specific cell lineages starting with the same initial state (MPs) and environmental conditions (initially no stimulation, followed by stimulation with CSF1 and IL7). Our results show two waves of gene activation for both myeloid and lymphoid factors. The first wave corresponds to the progenitor (GMP or CLP) expression programs, and the second one corresponds to terminally differentiated cells (macrophages or B cells) (Fig. 5B, Top and Middle). The evolution of the different cell populations (defined by the gene-expression signatures indicated in Dataset S4) was consistent with our logical simulations, with a rapid decrease of the MP population followed by the specification toward GMPs and CLPs and then by their differentiation into macrophages and B cells, respectively (Fig. 5B, Bottom). The proportions of myeloid and lymphoid cells were ~75 and 25%, respectively, in qualitative agreement with the higher proportion of myeloid cells present in the bone marrow (32). Tentatively, this asymmetry could be encoded in the regulatory circuitry rather than merely being the result of differences in proliferation rates. A sensitivity analysis further revealed that the proportion of lymphoid and myeloid cells was affected only by changes in the up-regulation rates of *Cebpa*, *Foxo1*, and E2a (Fig. S2I), supporting the key function of *Cebpa* and *Foxo1* in the commitment decision (E2a being required for *Foxo1* expression).

To obtain more comprehensive insights into the alternative trajectories underlying myeloid and lymphoid lineage specification, we clustered the logical states (Fig. 5A) to generate a hierarchical (acyclic) graph (28) in which all the states with a similar potential (i.e., leading to the same attractors or differentiated states) are

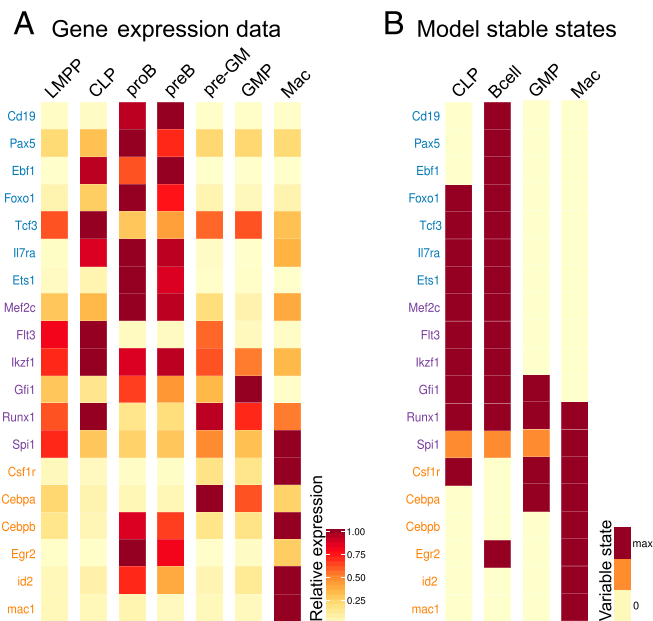

Fig. 4. (A) Gene-expression values (microarrays) in lymphoid/myeloid progenitors (LMPP), B cells, and macrophages (Mac) (29). These values are relative to the highest expression value. (B) Context-dependent stable states computed for the model. A yellow cell denotes the inactivation of the corresponding component, a red cell represents maximal activation (1 for Boolean components, 2 for *Spi1*), and an orange cell represents an intermediate level (1) for *Spi1*.

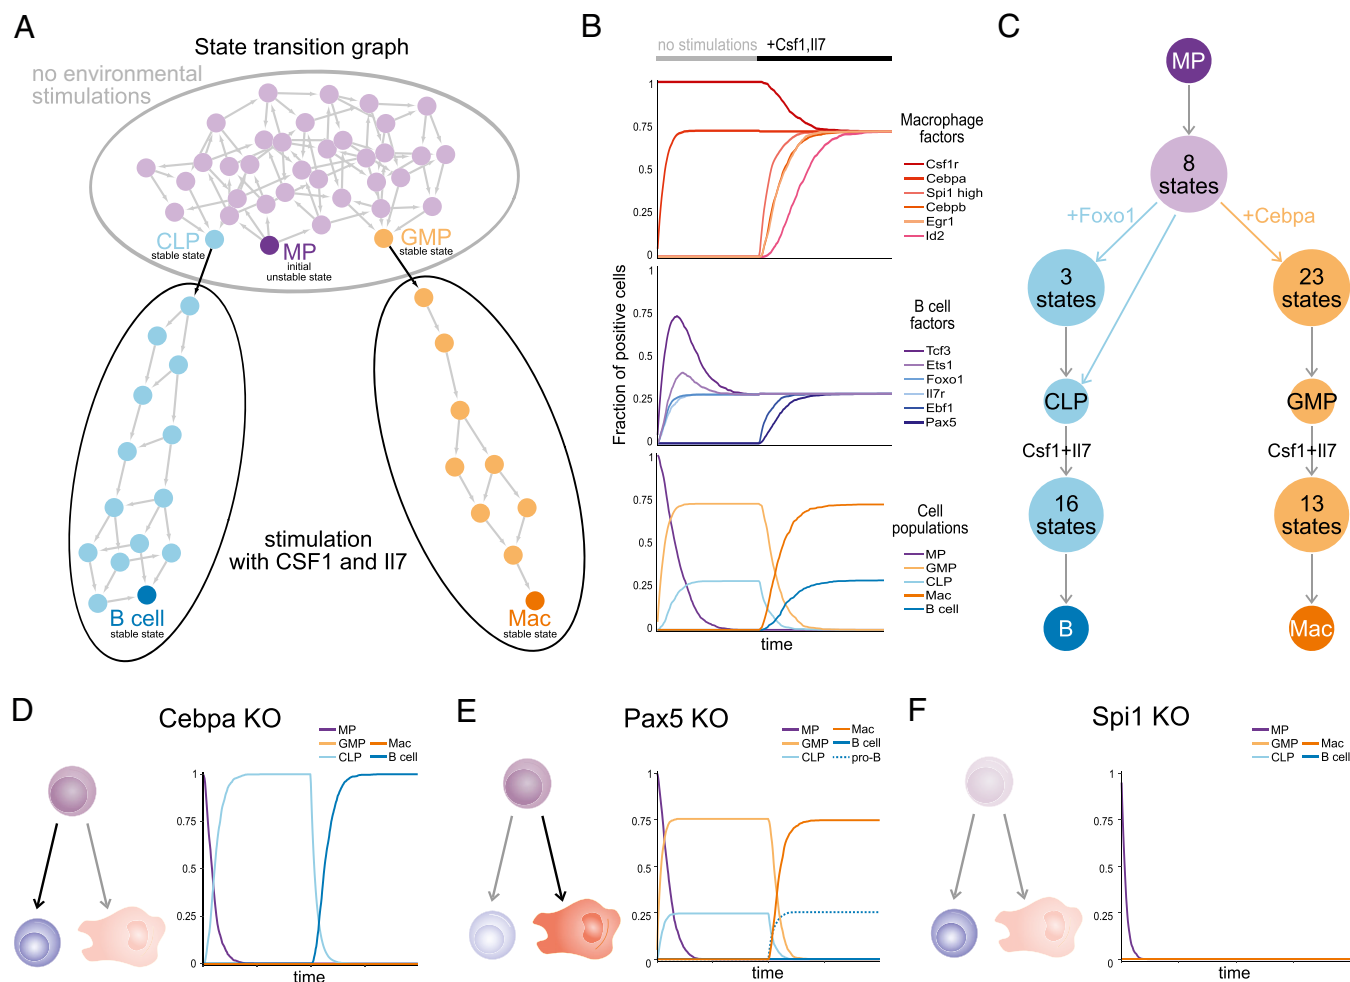

Fig. 5. (A) State transition graph generated by simulating the model starting from the unstable MP state in the absence of cytokine (Upper) and after the addition of CSF1 and IL7 (Lower Left and Lower Right). Nodes denote states, and arrows represent transitions between states. (B) Stochastic simulations showing the evolution over time, before and after cytokine exposition, of the fractions of cells expressing specific macrophage factors (Top), B-cell factors (Middle), and cell-type signatures (Bottom). The x and y axes represent time (in arbitrary units) and fractions of positive cells, respectively. (C) Hierarchical transition graph corresponding to the state transition graph in A. Nodes represent clusters of states, and arrows denote the possible transitions between the clusters. The labels associated with the edges highlight the crucial transitions involved in the decision between B-cell and macrophage specifications. (D–F) Schematic representations and stochastic simulations of the effects of Cebpa knockout (D), Pax5 knockout (E), or *Spi1* knockout (F) on the differentiation of MPs, compared with the wild-type situation in A and B. In the cartoons, the wild-type stable states (cell types) and transitions that are lost in each mutant are displayed using light gray arrows and shading. MP, B cells, and macrophages are represented in purple, blue, and red, respectively.

clustered in a single node (Fig. 5C). Interestingly, this analysis shows that the cell decision between GMPs and CLPs depends mainly on the concurrent activation of Cebpa and Foxo1, emphasizing the importance of these factors in early hematopoietic progenitor specification.

Simulation of Documented Genetic Perturbations. Next, we simulated the effects of well-documented gene loss-of-function experiments on progenitor cell specification. Our simulations faithfully recapitulated the effects of various published gene-ablation experiments (Dataset S5). For example, Cebpa knockout in MPs results in the loss of the stable states associated with GMPs and macrophages (Fig. 5D), in agreement with the reported impact in vivo (33). Pax5 knockout does not affect the formation of the progenitors but blocks the development of the B-cell lineage at the pro-B stage and prevents the acquisition of the terminal B-cell marker Cd19 (Fig. 5E), in agreement with published experimental data (34).

However, the simulation of *Spi1* knockout does not reproduce the reported viability of B cells in *Spi1*-knockout mice (35). This discrepancy arose because, in our model, *Spi1* is required for the

expression of the B-cell factors E2a, Ebf1, and Il7r. Introducing additional cross-activations between the B-cell factors and releasing the requirement of Runx1 for Ebf1 up-regulation and of Mef2c for Il7r activation could rescue the expression of the B-cell factors. When we refined the corresponding rules accordingly (Dataset S3), the resulting model showed a stable state corresponding to B-cell patterns in the *Spi1*-knockout condition. However, such patterns cannot be reached from a *Spi1*^{-/-} MP state, because the cells end up with a complete collapse of gene expression (Fig. 5F).

Dynamical Analysis of Transdifferentiation. Next, we analyzed in silico the transdifferentiation of pre-B cells into macrophages upon C/EBPα induction. We first simulated the behavior of B cells under a permanent induction of C/EBPα in the presence of CSF1 and IL7. The system converged toward a single stable state corresponding to macrophages, which does not further require induction of exogenous C/EBPα (Fig. S3A), in accordance with published reports (5).

We then focused on the effect of transient inductions of C/EBPα. We have previously shown with our β-estradiol-inducible pre-B-cell

line that a 24-h induction of *C/EBPα* followed by washout of the inducer was sufficient to trigger irreversible reprogramming (36). Shorter inducer exposure times led to the formation of two populations: one converting into macrophages, and the other initiating transdifferentiation but returning to a B-cell state. A simulation of this process testing all possible pulse durations at once (*Materials and Methods*) confirms that, depending on the duration of *C/EBPα* induction, B cells can be reprogrammed to macrophages or can go back to a B-cell state (the state transition graph for such simulations cannot be displayed because it contains more than 30,000 states).

Aiming at identifying the commitment point of reprogramming, we further analyzed the resulting hierarchical transition graph (Fig. 6A). Because endogenous *Cebpa* becomes activated very late during transdifferentiation (at about 48 h; see Fig. S3B), notably after the commitment point (~24 h), we focused on the *Cebpa*[−] states (i.e., with *Cebpa* = 0) leading to the sole macrophage stable state (Fig. 6A, Lower). Some of these states expressed *Foxo1*, suggesting that the inhibition of *Cebpa* by *Foxo1* can be overcome, in contrast with what happens during the specification of GMPs and CLPs from MPs (Fig. 5C). Interestingly, we found that these *Cebpa*[−] states show low constraints on B-cell factors, because only *Pax5* must be down-regulated. Furthermore, all *Cebpa*[−] states expressed *Cebpb* and *Spi1* at a high level, whereas *Pax5* was the only B-cell factor required to be inactivated. Finally, some states were found to be *Csf1r*[−], but only when *Gfi1* is silenced (along with its activator *Ikaros*, at least when its repressor *Egr2* is not expressed), because *Gfi1* can block high *Spi1* expression (21).

Turning to stochastic simulations, we observed the expected loss of B-cell and gain of macrophage phenotypes for both permanent and transient *C/EBPα*-induced expression (Fig. S3C). However, these more quantitative simulations also revealed some inconsistencies. (i) *Cebpa* is reactivated very rapidly; this discrepancy can be circumvented by lowering the kinetic rate of *Cebpa* up-regulation.

(ii) The timing of the repression of B-cell genes and that of the loss of CD19 marker roughly coincide; however, we observed that B-cell genes are transcriptionally repressed very rapidly (after 3 h; see Fig. S1C), whereas CD19 protein is lost only after 24 h (36). (iii) Our model also does not properly capture the fact that short *C/EBPα* pulses result in the loss of CD19⁺ cells, which are regained after *Cebpa* inactivation (36), suggesting that reversion of reprogramming is possible after short induction.

The last two points suggest that B-cell TFs are rapidly down-regulated at the transcriptional level but that the corresponding proteins are retained in transdifferentiating cells for longer times, facilitating reversion of the reprogramming. To address this possibility, we performed a ChIP-seq for Ebf1 at several time points upon permanent induction of *Cebpa*. Indeed, although Ebf1 RNA decreased by 50% after 3 h of *C/EBPα* induction (Fig. S1C), we observed that Ebf1 binding was lost only after 24 h of induction (Fig. 6B). We therefore added a delay in B-cell factor protein degradation to our model (*Materials and Methods*), resulting in a better fit with the observed timing of events during transdifferentiation for both permanent and transient *C/EBPα* induction (Fig. 6C).

In conclusion, our analysis suggests an important role for the *Egr2*-*Gfi1*-*PU.1*– and *C/EBPβ*-*PU.1*–positive loops in the irreversible commitment during transdifferentiation and emphasizes the importance of the balance between protein degradation and transcriptional regulation kinetics in the reversibility of the reprogramming.

Simulations of Combined Perturbations During Transdifferentiation.

Finally, we analyzed the effects of various TF gain-/loss-of-functions on *Cebpa*-induced reprogramming, combining *C/EBPα* induction with a knockdown of *Spi1* or *Cebpb* or with a constitutive expression of *E2a*, *Ebf1*, *Pax5*, *Foxo1*, or *Gfi1* (Fig. 7). As previously shown (26), only the *Spi1* knockdown is able to block

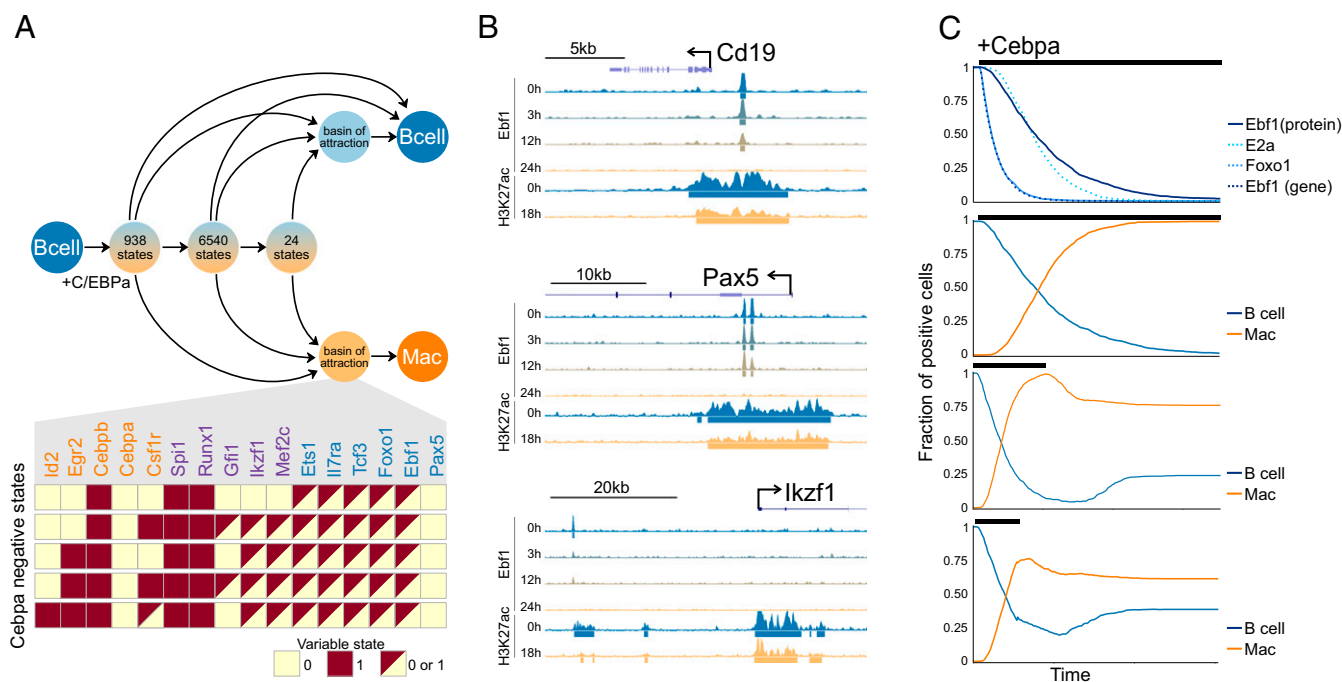

Fig. 6. (A, Upper) Hierarchical transition graph of the simulation of B-cell transdifferentiation upon transient *C/EBPα* expression, taking into account all possible *C/EBPα* pulse durations. Nodes represent clusters of states, and arcs correspond to transitions between these clusters. (Lower) *Cebpa*[−] states (rows) of the basin of attraction of the macrophage stable state. (B) ChIP-seq signals and peaks (under signal) in B cells (in blue, time point 0 h) and after induction of *C/EBPα* (at 3, 12, and 24 h). The vertical axes represent RPM (maximum, 5 RPM). (C) Stochastic simulations of the fraction of cells expressing different B-cell factors (Top Panel) and cell-population signatures (Lower Three Panels) during transdifferentiation upon permanent (Upper Two Panels) or transient (Lower Two Panels) *C/EBPα* ectopic expression. The corresponding induction durations (in arbitrary units) are indicated by the black lines above each panel.

Cell Culture. HAFTL (pre-B) cells and the C/EBP α -ER-containing cell derivative C10 were grown in Roswell Park Memorial Institute (RPMI) medium with L-glutamine supplemented with 10% (vol/vol) FBS, 1 \times penicillin/streptomycin, and 50 μ M β -mercaptoethanol. The RAW 264.7 (ATCC TIB-71) macrophage cell line was grown in DMEM with L-glutamine supplemented with 10% FBS and 1 \times penicillin/streptomycin.

Western Blot. Western blots were performed using C10 cells and RAW cells as previously described (22). More information can be found in *SI Materials and Methods*. The following antibodies were used at dilution of 1:1,000: Gfi1 (6C5 ab21061; Abcam), Egr2 (EPR4004 ab108399; Abcam), Egr1 (s-25, sc-101033; Santa Cruz), and GAPDH (6C5 sc-32233; Santa Cruz).

ChIP-Seq. ChIP-seq experiments were performed as described previously (45). DNA libraries were prepared using Illumina reagents and instructions and were sequenced on an Illumina Hi-Seq 2000 system. Data are available on the Gene Expression Omnibus (GEO) database under accession codes GSE86420 (Ebf1 and Foxo1 ChIP-seq) and GSM1290084 (previously published Cebpa ChIP-seq in Cebpa-induced B cells).

Ectopic Expression of TFs and Gene-Expression Quantitative PCR. Forced expression of the B-cell TF Foxo1 in RAW cells was performed using retrovirus. More information can be found in *SI Materials and Methods*.

ACKNOWLEDGMENTS. We thank the staff of the computing platform at the Institut de Biologie de l'Ecole Normale Supérieure for support in hardware and software maintenance; the flow cytometry facility at the Center for Genomic Regulation (CRG)/Universitat Pompeu Fabra for help with cell sorting; the genomics facility of the CRG for sequencing; and Anna Niarakis, Ralph Stadhouers, and Tian Tian for helpful comments regarding earlier versions of this paper. S.C. is supported by a scholarship from the French Ministry of Superior Education and Research. J.L.S.O. was supported by a grant from the Ministry of Economy, Industry, and Competitiveness (MINECO) (IJC-2014-21872). B.D.S. was supported by a long-term fellowship from the European Molecular Biology Organization (EMBO) (#ALTf 1143-2015). The T.G. laboratory was supported by Grant 282510 from the European Union Seventh Framework Program BLUEPRINT and Fundacio la Marato TV3. This work also was supported by the Spanish Ministry of Economy and Competitiveness, Centro de Excelencia Severo Ochoa 2013–2017 and the Centre de Recerca de Catalunya (CERCA) Programme, Generalitat de Catalunya.
